Abstract

Reliance on fossil fuels is causing unprecedented climate change and is accelerating environmental degradation and global biodiversity loss. Together, climate change and biodiversity loss, if not averted urgently, may inflict severe damage on ecosystem processes, functions and services that support the welfare of modern societies. Increasing renewable energy deployment and expanding the current protected area network represent key solutions to these challenges, but conflicts may arise over the use of limited land for energy production as opposed to biodiversity conservation. Here, we compare recently identified core areas for the expansion of the global protected area network with the renewable energy potential available from land-based solar photovoltaic, wind energy and bioenergy (in the form of Miscanthus x giganteus). We show that these energy sources have very different biodiversity impacts and net energy contributions. The extent of risks and opportunities deriving from renewable energy development is highly dependent on the type of renewable source harvested, the restrictions imposed on energy harvest and the region considered, with Central America appearing at particularly high potential risk from renewable energy expansion. Without restrictions on power generation due to factors such as production and transport costs, we show that bioenergy production is a major potential threat to biodiversity, while the potential impact of wind and solar appears smaller than that of bioenergy. However, these differences become reduced when energy potential is restricted by external factors including local energy demand. Overall, we found that areas of opportunity for developing solar and wind energy with little harm to biodiversity could exist in several regions of the world, with the magnitude of potential impact being particularly dependent on restrictions imposed by local energy demand. The evidence provided here helps guide sustainable development of renewable energy and contributes to the targeting of global efforts in climate mitigation and biodiversity conservation.

Introduction

The world is facing two environmental challenges of massive scale, global climate disruption (IPCC, 2013) and the biodiversity collapse (Dirzo et al., 2014; Pimm et al., 2014). Heavily based on fossil fuel sources, modern energy policies are an undisputable driver of climate change and air pollution (IPCC, 2013), which represent major environmental risks to human health (World Health Organization, 2013). At the same time, fossil fuel extraction adds to the many drivers, such as habitat loss and fragmentation, largely responsible for the current biodiversity decline (Butt et al., 2013; Secretariat of the Convention on Biological Diversity, 2014). Failure to address climate change and biodiversity loss now may seriously compromise future possibilities for successful action (IPCC, 2013; Secretariat of the Convention on Biological Diversity, 2014). This urgency has been perceived by the international community, and two targeted policy agendas for achieving medium-term goals have been formalized: for climate change mitigation, the Kyoto protocol, followed by the Copenhagen Accord in 2009 adopted under the United Nations Framework Convention on Climate Change; and for biodiversity conservation, the Aichi biodiversity targets...
becoming increasingly scarce (Wise for development and biodiversity conservation is (Brook & Bradshaw, 2014). Because land area available more land-use intensive than other energy sources from fossil fuel extraction and combustion (IPCC, 2011; direct and indirect pressures on biodiversity derived REN21, 2014) while potentially alleviating forthcoming direct and indirect pressures on biodiversity derived from fossil fuel extraction and combustion (IPCC, 2011; Butt et al., 2013). As a disadvantage, RE is typically more land-use intensive than other energy sources (Brook & Bradshaw, 2014). Because land area available for development and biodiversity conservation is becoming increasingly scarce (Wise et al., 2009; Foley et al., 2011), there is a serious risk that goals to mitigate climate change will conflict with goals to protect biodiversity (e.g. by pursuing the Aichi Target 11 of the CBD: expanding the global protected area [hereafter PA] network to cover 17% of land by 2020). Recent years have seen an unprecedented growth in deployment of RE, particularly wind energy, solar and bioenergy (IPCC, 2011; REN21, 2014). As this trend is projected to continue, vast regions may become affected by RE development (IPCC, 2011; REN21, 2014).

Key policy decisions will soon be made regarding where to allocate land for RE production as opposed to land to be protected for biodiversity conservation, among other uses. Land restrictions will involve trade-offs between development and conservation, particularly in those regions that support high potential for RE production and high levels of biodiversity. While there is a recent surge of global studies addressing the PA network expansion for achieving the CBD targets (Joppa et al., 2013; Pouzols et al., 2014; Venter et al., 2014), none of them consider the practical constraints imposed by the competition for land with increasing energy production through renewables, despite these being rapidly expanded across the world and being characterized by high land-use intensity (IPCC, 2011). Indeed, only a few studies have assessed the impact of energy sprawl on major habitats and ecosystems at the regional level (McDonald et al., 2009; Northrup & Wittemeyer, 2013), and we are aware of no global studies that spatially describe the overlap between areas of high potential for RE development and biodiversity conservation (but see Butt et al., 2013 for a study on fossil fuel impacts on biodiversity). The rapid expansion of RE deployment and its associated high land-use intensity means there is an urgent need to identify both areas where conflicts between RE development and biodiversity may arise and areas of opportunity for development with low associated costs to biodiversity. Ultimately, such information can serve as guidance for policy decisions to strategically harvest RE while promoting biodiversity protection.

Here, we present a spatial analysis of overlap between areas of highest priority for biodiversity conservation and areas of highest potential for development of RE. We compare priority areas for the expansion of the global PA network (as stated by the Aichi target 11; and identified by Pouzols et al., 2014) with potential for the three most rapidly expanding REs, land-based wind turbines, solar photovoltaic panels and dedicated bioenergy crops (in the form of Miscanthus × giganteus; REN21, 2014). While doing so, we consider RE potential within current PAs, within the top 17% and 30% priority areas for global PA network expansion, and the remaining land with lowest priority for PA expansion. Furthermore, we consider scenarios where net RE production potential is unconstrained versus constrained by production costs, carbon emissions and energy demand. We identify the areas with highest risk of conflict between PA network expansion and development of each of the three REs. We also identify areas that may represent opportunities for high RE yields at relatively low costs for biodiversity conservation. We present analysis of the extent of possible conflicts and opportunities at the global and continent level, by quantifying the percentage of net RE potential within current PAs, the 17% and 30% highest priority areas for PA expansion and the rest of the global land area. Finally, we compare present energy consumption levels with RE potential within each priority class for PA network expansion.

Materials and methods

We analyse the spatial overlap between two classes of global data: (i) priority areas for the global PA network expansion (Pouzols et al., 2014) and (ii) potential energy production maps for each of the three main land-based REs, namely bioenergy (in the form of Miscanthus × giganteus), solar photovoltaic and wind (hereafter named bioenergy, solar PV and wind energy, respectively; Pogson et al., 2013). All data and analyses were restricted to the terrestrial surface. For each RE source, we consider restrictions on net energy production potential imposed by the financial costs of energy production, associated carbon emissions and local energy demand (see below for further details). For the PA expansion, we use a four-level classification of land: current PAs; top 17% expansion areas (corresponding to the Aichi Target 11); secondary PA expansion areas (top ranked 17–30% areas); and the rest of the landscape (lowest ranked 70%) (Pouzols et al., 2014).
Global protected area expansion data

We used the final output (available at: http://avaa.tdata.fi/web/chig/gpan) of a comprehensive global analysis that ranked the world’s currently unprotected land according to its potential for expanding and filling gaps in the current PA network as stated by the Aichi Target 11 of the CBD (Pouzols et al., 2014). The underlying original data used in this study to derive the PA expansion map included range maps of all red-listed terrestrial vertebrates (24,757 species assessed under the IUCN red list) and the areas covered by each of the world’s 827 ecoregions as defined by WWF (World Wide Fund for Nature). In the analysis, species were weighted based on their threat status, and species ranges were filtered by present and predicted land-use intensity (Van Asselen & Verburg, 2013). The analysis took as a starting point the current PA network (the World Database on Protected Areas) and used the spatial conservation prioritization tool Zonation v.4 to identify the priority areas for PA network expansion to 17% of the global land area (Moilanen et al., 2005, 2014). The process iteratively ranks all areas from lowest to highest priority for conservation, guided by principles such as balance between representation of all input features, minimization of aggregate extinction rates and preference for spatial aggregation (Pouzols et al., 2014).

Renewable energy data

We used global maps of potential for RE production as presented by Pogson et al. (2013). The RE sources considered were as follows: land-based wind energy, solar PV and bioenergy from dedicated plantations. For the latter, the potential was based on the growth of Miscanthus × giganteus, a nonfood crop, with C₄ photosynthesis, that can also be grown on marginal land and is characterized by lower land-use intensity than other bioenergy crops (IPCC, 2011) such as sweet sorghum and sugar cane. Miscanthus does not grow well at high latitudes, meaning that the bioenergy potential we consider in this study is mostly representative for bioenergy production in the tropical and temperate regions. At higher latitudes other crops, such as short rotation trees (e.g. poplars and willows), may provide slightly higher bioenergy yield per land unit than Miscanthus (Beringer et al., 2011). However, our main aim is to relate RE potential with global PA network expansion, and because both highest biodiversity and bioenergy potentials concentrate in tropical and subtropical areas (Gaston, 2000; Pogson et al., 2013), using only Miscanthus allows adequate approximation of the conflict and opportunity between RE development and biodiversity conservation. An established crop model (Hastings et al., 2009) was used to predict the bioenergy potential from Miscanthus based on meteorological and soil data at the global level (Pogson et al., 2013).

For solar, only photovoltaic panels were considered. Solar PV has the widest deployment potential (e.g. compared to water heating panels and concentrating solar panels), thereby providing a good representation of the overall solar power potential for energy production globally. Solar potential was predicted by incident radiation based on latitude and time of the year and considering cloud cover (Hastings et al., 2009; Pogson et al., 2013). Wind power potential was calculated based on incident wind harnessed by a horizontal axis wind rotor (for further details, see Pogson et al., 2013). Data for solar PV and bioenergy potential were lacking for Greenland. However, this area represents very marginal potential for solar and bioenergy given the high latitude, and also for expansion of biodiversity conservation (as most of Greenland is protected already), thereby having little impact at the global level.

Here, we focused on RE sources of wide global expansion potential in the terrestrial realm, thereby excluding offshore wind energy and hydropower from the analysis. Although offshore wind energy deployment has been growing rapidly during recent years (REN21, 2014), its associated impacts on biodiversity are yet to be fully understood (Inger et al., 2009; Wilson & Elliott, 2009). Hydropower is excluded because, besides being very localized and restricted, its rate of expansion is declining as most of the potential sites have been already exploited in many, although not all (Finer & Jenkins, 2012), regions of the world (World Commission on Dams, 2000; Boyle, 2012).

Production costs per unit energy were estimated considering the full life cycle of each of the three RE technologies, while temporal changes in factors affecting costs (aside from the discount rate) were neglected (Pogson et al., 2013). For Miscanthus, the costs of land rent, crop establishment, harvest, storage and transport were considered, while only land rent and deployment costs were considered for solar PV, and land rent, deployment, maintenance and insurance costs for wind energy (Pogson et al., 2013). Carbon emissions were estimated considering farming inputs that rely on fossil fuels for Miscanthus, while for solar and wind energy, emissions were estimated accounting for the production process of the technology to be installed (Pogson et al., 2013).

A restriction imposed by power demand was applied to model distributed energy production where energy is produced and used locally. This was implemented by restricting the power generation per unit area within each grid cell so that it does not exceed the power consumption per unit area within that cell. We combined data on country-specific power use (http://data.worldbank.org) with spatial population density data (http://sedac.ciesin.columbia.edu/gpw) to derive a measure of power use density (GJ/ha/year). For countries lacking specific power use data (see a list in Table S1), we used the world average power use value. The derived measure of power use density was used as an upper limit to restrict power generation in each grid cell. This restriction implies that energy is not transmitted between grid cells (i.e. the energy is used locally within each 0.5 degree square grid cell, which corresponds to roughly 56 km at the equator), but no assumption is made of the availability of land within each cell (but see below for consideration of total land available). Therefore, as cells with high power demand are likely to have less land available, there is an implicit assumption that some transmission may occur between nearby grid cells, as cells with low power demand (which would be more heavily restricted in the present study) would in reality be likely to have more land available to service nearby cells with high demand. No consideration is made of existing land use; this is supported by
growing evidence on indirect land-use change in several regions of the world, including conversion of tropical rainforests to bioenergy crops (Fargione et al., 2008; Koh & Wilmers, 2008). In addition, if, for example, current tropical forest land was considered as unavailable for RE development, this would imply an unsupported assumption that governance of this habitat is strong enough to prevent its conversion (Verboug et al., 2013). This would bias results by underestimating threats from RE on forested habitats, and vice versa for open landscapes.

As an estimate of total global power consumption, we used values provided by the U.S. Energy Information Administration for year 2010 (downloaded from www.eia.gov). When comparing RE potential with power consumption, we proceeded under the assumption that only 1% of the overall land of a region is allocated for production of each of the three RE sources within areas where at least some energy production potential is available, and in turn concentrated within each area of different importance for biodiversity protection. Although this percentage is somewhat arbitrary, it is sufficient for realistic analyses of the marginal benefits and costs of different RE alternatives; any other value than 1% could also be easily evaluated via a simple multiplication.

To quantify the RE potential within each area of different importance for biodiversity protection, we extracted the areas belonging to (i) the current protected areas (up to 11% of the terrestrial areas), (ii) the proposed globally important expansion areas (from 11% to 17%), (iii) the global high priority areas (from 17% to 30%) and (iv) the rest of the landscape from the original analysis results (see above and Pouzols et al., 2014). For simplicity, we hereafter call ‘top biodiversity areas’ all areas within the top 30% priorities for biodiversity protection (i.e. current PAs, and their expansions to 30% coverage). Correspondingly, we will refer to energy potential within and outside these top biodiversity areas.

In this study, we use two extreme scenarios, one where RE potential is not constrained by any external factors, and one where RE is constrained, in a highly restrictive manner, by costs, carbon and local energy demand (we also show results for intermediate scenarios based on combinations of the restricting factors in the supplementary materials). In reality, research and development is advancing rapidly (Lloyd & Forest, 2010; REN21, 2014), and solutions may partly alleviate the above restrictions on energy storage and transport (Trieb et al., 2012; Li et al., 2014) in the short to medium term, particularly for solar PV (Fthenakis et al., 2009; Stodola & Modi, 2009; Lloyd & Forest, 2010; Grossmann et al., 2013, 2014).

Results

Unrestricted RE potential and biodiversity protection

At the global level, bioenergy (here represented by Miscanthus × giganteus) appears to be the energy source that, among those considered here, has the highest potential to conflict with biodiversity protection given its high potential within tropical areas that are well recognized as key for biodiversity (Fig. 1). We quantify the extent of this potential conflict. At the global level, approximately half of the energy production potential from bioenergy is located within the top biodiversity areas (i.e. the highest ranked 30% terrestrial land for biodiversity protection; Figs 1 and 2). Three quarters of this potential falls on unprotected land thereby representing a potentially high threat to biodiversity (Fig. 2). Comparing continents, the overlap between bioenergy potential and top biodiversity areas varies from a very large overlap in Central America, where 86% of energy potential falls within the top biodiversity areas, most of which are currently unprotected, to lower overlap, approximately 40%, in Africa, Europe and North America (Figs 1 and 2).

The potential conflict arising from overlap between biodiversity conservation and energy production appears lower for wind energy and solar PV than for bioenergy, with only one-third of their respective global potential located within the top biodiversity areas (Figs 1 and 2). However, in Central America the overlap between top biodiversity areas with wind energy and solar PV, as for bioenergy, is very high (77 and 75% of potential within top biodiversity areas, respectively). Elsewhere, solar PV may represent a threat in South America, where 47% of its potential is included within top biodiversity areas, 71% of which remain currently unprotected (Figs 1 and 2).

Demand, costs and carbon restricted RE potential and biodiversity protection

A restriction scenario for energy production potential based on local energy demand, production costs and carbon emissions caused a shift in the pattern of conflict especially for solar PV and wind energy (Figs 3 and 4). Unavoidably, these restrictions result in energy production being spatially concentrated towards areas of both high energy potential and high energy demand, which are more likely to coincide with areas with high biodiversity (Fig. 3). Compared to the unrestricted scenario, the fraction of solar energy within the top biodiversity areas increased globally from 32% to 41%, and for wind energy from 31 to 44% (Fig. 4). This shift was largely due to the energy demand cap on power potential in areas of low human density and of least importance of biodiversity, such as high-latitude regions for wind energy, and desert or dry lands at low latitudes for solar. Comparing continents, restriction by demand, costs and carbon resulted in a marked increase in wind energy potential fraction within the 17% areas of highest importance for PA expansion in Africa, Asia, Australia and South America. For solar, a change compared to the unrestricted scenario was most noticeable in Asia, Australia and South America, in which conflict with biodi-
versity areas increased following restriction on energy potential.

We also show results for intermediate scenarios based on restrictions by costs, by carbon, and by costs and carbon, and by demand only (see Figs S1–S9). It is clear from these intermediate scenarios that a carbon and/or cost restrictions yield almost identical results to the unrestricted scenario in terms of magnitude of conflict between biodiversity and energy production. Conversely, a restriction by local demand only causes an increase in the conflict between biodiversity and solar PV or wind energy, which now have similar percentages of energy concentrated within and outside the top biodiversity areas. Overall, these results highlight that bioenergy represents a potentially high risk to biodiversity irrespective of considerations related to costs, car-

Fig. 1 Overlap between unrestricted power generation potential for (a) bioenergy (in the form of Miscanthus × giganteus), (b) wind energy and (c) solar photovoltaic (GJ/ha/year; red colour gradient, see legend) overlapped to current PAs (Protected Areas; in green shading) and global top 17% areas for PA expansion (blue shading). Areas with no power generation are in grey. For bioenergy and solar, no data were available for Greenland.
bon and transport of energy. On the other hand, solar PV and wind energy may represent more opportunities than threats under a scenario of unrestricted energy generation, but their potential risk to biodiversity increases when energy production is restricted by local energy demand (i.e. energy transmission is minimal).

**RE potential, energy consumption and biodiversity protection**

Under the unrestricted scenario, it is evident that arbitrarily using only 1% of land for energy production in turn within each of the four land classes of different value for biodiversity protection, solar PV could potentially provide all of the energy that the global society currently consumes (Fig. 5). This outcome is apparent for each of the four land classes considered, including the land outside of the top 30% best areas for biodiversity protection (compare Fig. 5 two rightmost panels to the top). Conversely, developing 1% of land for unrestricted bioenergy or wind energy production would contribute less than 10% of global energy consumption (compare Fig. 5 two leftmost panels with the rightmost panel to the top). However, when restrictions relating to local energy demand, costs and carbon are simultaneously imposed on RE potential, it is clear that none of the three RE sources could provide any measurable contribution towards energy consumption globally or regionally (Fig. 5, lower row), again assuming development of only 1% of land. Across all continents, utilizing 1% of land for any of the three RE sources restricted by costs, carbon and demand, would only contribute less than 0.5% of the regional total energy consumption. The restriction imposed by local energy demand most significantly limits energy provision by RE, whereas restrictions by costs and carbon only have minor impacts (see Fig. S9), emphasizing the need for developing energy transport infrastructure.

**Discussion**

We combine data on global distribution of biodiversity with data on rapidly expanding land-based renewable energies to identify areas of conflict between biodiversity and energy development. We show that global key areas for biodiversity protection may be under threat from increasing renewable energy development in the near future. The magnitude of risk is dependent on the type of RE source harvested, the restrictions imposed on energy harvest and the region considered, with Central America appearing at particularly high potential risk from RE development. When no restrictions on the extraction of RE apply, we identify a major potential threat to biodiversity from bioenergy cultivation, while the potential impact of wind energy and solar PV appears comparatively lower. However, these differences are reduced when energy potential is restricted by external factors, in particular by local energy demand. Overall, we found that areas of opportunity for developing solar PV and wind energy with little harm to biodiversity could exist in several regions of the world, although without conversion of large land areas and long-scale power transmission, the contribution to satisfying existing demand is very low. In contrast, areas of opportunity for bioenergy production in land with low priority for biodiversity protection are scarce, irrespective of any additional external factors restricting energy production potential. This result arises from the fact that productive land in the tropical regions is usually good for biodiversity as well as for bioenergy generation (Gaston, 2000; Koh & Wilcove, 2008; Pogson et al., 2013).

Fig. 2 Percentage (relative to the total potential of each source) of unrestricted power generation potential available for bioenergy (in the form of Miscanthus × giganteus), wind energy and solar photovoltaic summarized by continents and globally. The bars show generation potential within current PAs (Protected Areas; black section of each bar), top ranked areas for 17% PA expansion (dark grey), 17–30% highest ranked areas (light grey) and for the remaining 70% of the landscape (white).
Conflicts and opportunities for biodiversity protection and RE development

We find that bioenergy production has potential to severely harm biodiversity, because half of its global production potential is concentrated within the top biodiversity areas (i.e. the top ranked 30% of land of highest priority for biodiversity protection). This outcome was confirmed even under the scenario constrained by costs, carbon and energy demand. The conflict between bioenergy production and biodiversity protection is particularly striking at low latitudes (Fig. 1), where many global biodiversity hotspots have been identified (Myers et al., 2000). Many hotspots are

© 2015 The Authors. *Global Change Biology Bioenergy* Published by John Wiley & Sons Ltd, 8, 941–951
already under high pressure, rapidly losing their native
vegetation because of land conversion (Sloan et al., 2014). Sprawl of bioenergy production into these areas
would further accelerate loss of many irreplaceable
ecosystems (Koh, 2007; Fargione et al., 2008; Gibson
et al., 2014), thereby undermining the fundamental
objectives of the UN Convention on Biological Diversity.
Also, areas of high bioenergy potential substantially
overlap key agricultural areas recently identified as hav-
ing high potential for closing the global crop yield gap
(West et al., 2014). Furthermore, looking at the relatively
minor total energy contribution available from bioen-
ergy (Fig. 5), it becomes clear that the benefits of bioen-
ergy contributing towards global power consumption
will largely be overturned by its dramatic environmen-
tal costs.

© 2015 The Authors. Global Change Biology Bioenergy Published by John Wiley & Sons Ltd, 8, 941–951
Contrasting threats to biodiversity from wind energy and solar appear smaller than those from bioenergy: around two-thirds of total unrestricted energy generation potential from solar and wind energy falls outside top biodiversity areas. Furthermore, unlike bioenergy, solar and wind energy to some extent allow other uses of the same land (IPCC, 2011). However, the results of the scenario including a restriction based on costs, carbon and energy demand call for caution also with these two REs, as their threat to biodiversity may reach a level similar to that posed by bioenergy (Fig. 4). Furthermore, as their potential for power generation is far greater than from bioenergy, they may also pose a greater threat to biodiversity, despite having proportionally lower potential in areas of high biodiversity.

Ultimately, solar power could provide by far the best combination of benefits compared to environmental costs, at least if restrictions imposed by energy transport are gradually lifted (i.e. shifting from the demand constrained to the unconstrained scenario). Under the (optimistic) unconstrained energy scenario, utilizing only 1% of land outside of top biodiversity areas for solar production could meet the total global power consumption. However, these benefits are almost completely cancelled if the solar power contribution is restricted by local energy demand. This scenario represents the other extreme of a continuum, where a perhaps too strict restriction is applied (little energy transport is allowed). We believe that the reality lies somewhere in between these two extremes, and the results highlight the importance of energy transport infrastructure to allow RE to be deployed while minimizing adverse impacts on biodiversity. Sustainable solar development is likely to be highly relevant for regions such as Asia and the USA, which host large areas of high biodiversity value and where solar photovoltaic markets are expanding at unprecedented rates (REN21, 2014). It is however important to note that solar PV generates electricity, therefore other sources of energy for transport and heating (among others) should also be considered. A diversification of the energy sources harvested is also relevant in the light of the variability in space and time (particularly for solar and wind energy) of each renewable energy source (IPCC, 2011).

While having lower harmful potential impacts on biodiversity compared to bioenergy, the contribution of land-based wind energy towards global power consumption appears limited even under no restrictions on energy generation. However, in coastal regions offshore wind energy (IPCC, 2011; REN21, 2014) would have additional potential that was not considered in this land-based assessment.

Among continents, Central America emerges as a single distinct hotspot of conflict. There, most of the potential for bioenergy (86%), but also for wind energy and solar PV (77% and 75%), is concentrated within top biodiversity areas, many of which are presently unprotected. The Mesoamerican biodiversity hotspot that runs through this region also is a major biodiversity corridor between North and South America (Myers et al., 2000). RE development in this region, if not wisely sited, could hasten direct loss and fragmentation of pristine habitats and also facilitate other indirect threats to biodiversity. Following RE development, increased accessibility to previously remote and isolated areas could facilitate the spread of disease, invasive species and unsustainable harvest of wildlife and trees (Peres & Lake, 2003; Northrup & Wittemyer, 2013; Olson et al., 2013).

We acknowledge that the data underlying this study have some potential limitations. The data on priority areas for biodiversity conservation are restricted to vertebrates only (Pouzols et al., 2014), whereas groups such as plants (Joppa et al., 2013) and invertebrates could be relevant. Nevertheless, the highest priority areas identified by Pouzols et al. (2014) were also found to have major overlap with known biodiversity hotspots, as well as key biodiversity areas and centres of plant diversity (see Appendix S1 in Pouzols et al., 2014). Despite past progress and future prospects regarding PA effectiveness and expansion (Laurance et al., 2012; Geldmann et al., 2013; Watson et al., 2014), the future of biodiversity is still heavily reliant on measures implemented outside PAs (Rodrigues et al., 2004; Joppa et al., 2013; Butchart et al., 2015). To this end, our working assumption of only 1% of land to be used for RE generation leaves ample operational space for biodiversity conservation in complex socio-ecological landscapes outside PAs, which is also a key objective set by the United Nations CBD targets 5, 7 and 8 (Secretariat of the Convention on Biological Diversity, 2014). Future research could include different energy transport distances, representing possible future energy transport infrastructures, as this proved to be a critical constraint in our scenario analysis.

We caution that evaluation of impacts, particularly for solar PV, is still in their infancy, and further research into this field is strongly and urgently needed to forecast possible unexpected environmental impacts and to develop best management practices and careful spatial planning (Sutherland et al., 2010; Katzner et al., 2013; Northrup & Wittemyer, 2013). This should be done on a case-by-case basis, but particularly when development is to take place in areas with high biodiversity value. In addition, technology advances in the three RE methods considered here are fast moving with the result that in future higher energy output per ha and lower GHG emission per energy unit being possible. For example, solar panel efficiencies of up to 25% are now technically
possible, seed-based propagation of Miscanthus genotypes with higher energy yields is being developed, and wind energy generation technology is evolving quickly (IPCC, 2011; REN21, 2014).

We pinpoint major areas of conflict where fine scale studies that focus on impacts of RE deployment on biodiversity should be conducted, and conservation efforts should be targeted. Clear examples of such areas are Central America and South-East Asia, where alternative and diversified energy sources should be considered to satisfy a growing demand for energy, mitigate climate change and preserve biodiversity (Brook & Bradshaw, 2014). We show that RE alternatives have very different biodiversity impacts and net energy contribution, with threats mostly posed by bioenergy sprawl, and opportunities mostly represented by solar, the extent of which is however highly dependent on restrictions imposed by energy storage and transmission. Several developing and emerging countries in Central and South America, Africa and Asia have recently enacted targeted RE policies, whereas most countries in North America, Europe and Australia did so at an earlier stage (REN21, 2014). The evidence provided here will help to guide sustainable development of RE, thereby contributing towards reaching targets for global climate mitigation and biodiversity conservation. RE should however not be seen as a panacea, but rather as an opportunity that, along with diversified energy sources should be considered to mitigate climate change and maintain biodiversity (Brook & Bradshaw, 2014).

Acknowledgments

Appendix S1. This file includes all of the supporting material associated to the printed version of the main paper by Santangeli et al. “Global change synergies and trade-offs between renewable energy and biodiversity” published in Global Change Biology Bioenergy.

Figure S1. Overlap between power generation potential constrained by costs for (a) bioenergy (in the form of Miscanthus × giganteus), (b) wind energy and (c) solar photovoltaic (GJ/ha/year; red colour gradient, see legend) overlapped to current PAs (Protected Areas; in green shading) and top areas for 17% global PA expansion target (blue shading).

Figure S2. Percentage (relative to the total potential of each source, rather than demand) of power generation potential constrained by costs available for bioenergy (in the form of Miscanthus × giganteus), wind energy and solar photovoltaic by continent and globally.

Figure S3. Overlap between power generation potential constrained by carbon for (a) bioenergy (in the form of Miscanthus × giganteus), (b) wind energy and (c) solar photovoltaic (GJ/ha/year; red colour gradient, see legend) overlapped to current PAs (Protected Areas; in green shading) and top areas for 17% global PA expansion target (blue shading).

Figure S4. Percentage (relative to the total potential of each source, rather than demand) of power generation potential constrained by carbon available for bioenergy (in the form of Miscanthus × giganteus), wind energy and solar photovoltaic by continent and globally.

Figure S5. Overlap between power generation potential constrained by costs and carbon for (a) bioenergy (in the form of Miscanthus × giganteus), (b) wind energy and (c) solar photovoltaic (GJ/ha/year; red colour gradient, see legend) overlapped to current PAs (Protected Areas; in green shading) and top areas for 17% global PA expansion target (blue shading).

Figure S6. Percentage (relative to the total potential of each source, rather than demand) of power generation potential constrained by costs and carbon available for bioenergy (in the form of Miscanthus × giganteus), wind energy and solar photovoltaic by continent and globally.

Figure S7. Overlap between power generation potential constrained by demand for (a) bioenergy (in the form of Miscanthus × giganteus), (b) wind energy and (c) solar photovoltaic (GJ/ha/year; red colour gradient, see legend) overlapped to current PAs (Protected Areas; in green shading) and top areas for 17% global PA expansion target (blue shading).

Figure S8. Percentage (relative to the total potential of each source, rather than demand) of power generation potential constrained by demand available for bioenergy (in the form of Miscanthus × giganteus), wind energy and solar photovoltaic by continent and globally.

Figure S9. Total energy generation potential (EJ per year; using original data from Pogson et al., 2013) by continent and for the world assuming that 1% of each region’s terrestrial land with at least some energy generation potential is developed for renewable energy production in turn within each of four main land classes of different importance for biodiversity protection: currently protected areas (PAs; in green), highest ranked areas for PA network expansion to 17% (blue), next highest ranked biodiversity areas (17–30%; yellow), and the remaining 70% of the landscape (grey).

Table S1. List of countries lacking power use data which was used to produce the demand restricted energy potential.
